Cross pinning versus lateral pinning in type III supracondylar fracture: a retrospective analysis

INTRODUCTION

Supracondylar fracture of humerus in children is one of the most common fractures seen in the first decade of life. The modified Gartland system is most often used for classification of supracondylar humeral fractures in children (Table 1).1

Type III injuries are completely displaced with both cortices fractured. Wilkins subdivided Type III injuries according to the coronal plane displacement of the distal fragment into Posteromedial or Posterolateral injuries.2 This modification was clinically helpful in identifying complications from injury in problems with treatment. The high incidence of residual deformity and the potential for neurovascular complications makes supracondylar humerus fractures a serious injury.

The non-operative management of type III supracondylar fractures of humerus including Dunlop skin traction,
skeletal traction and cast application has historically been associated with a greater incidence of failure to obtain and maintain the fracture reduction and have higher complication rates.\textsuperscript{3-6}

The gold standard treatment for displaced Supracondylar fractures is closed reduction percutaneous pinning (CRPP). The debate persists in optimal pin configuration (Figure 1). Though crossed pinning provides increased biomechanical stability, it simultaneously carries the risk of iatrogenic ulnar nerve injury IUNI (5%) due to medial pin placement.\textsuperscript{7}

\textbf{Figure 1: Criss-cross pinning versus lateral pinning.}

Studies has shown lateral pinning done with proper technique provides same stability and avoids IUNI.\textsuperscript{7} The stability is increased by maximal separation of the pin at the fracture site and also where they cross the fracture site (Figure 2).\textsuperscript{7}

\textbf{Figure 2: A and B-Correct positioning of lateral-entry pins.}

The present study is to compare whether lateral pin construct, if placed properly, can provide the same stability like cross pinning, at the same time avoiding the possibility of IUNI.

\section*{METHODS}

A retrospective analysis in 27 children treated with lateral pinning and 28 children with cross pinning between June 2013 to June 2015 was done. There were 16 boys and 11 girls treated with lateral pinning. In cross pinning group, there were 17 boys and 11 girls. In both the groups there were no children with any preoperative neurological deficits. Left side was predominant in both sexes. We had an inclusion and exclusion criteria.

\textbf{Inclusion criteria}

All type III supracondylar fractures of humerus of either side in either sex, in children between the age group of 2-12 years.

\textbf{Exclusion criteria}

a) Flexion type, b) Previous fractures in same limb, c) Type I and II fractures, d) Fracture requiring open reduction, e) With vascular injury, f) Any child with preoperative nerve injuries.

Immediately after the patients arrival to the hospital a detailed clinical examination including a thorough neurovascular assessment was carried out. Standard antero-posterior and lateral radiographs of the involved elbow were taken and the fracture type was noted. The cases were treated on an emergency basis with closed reduction and percutaneous pinning, under the guidance of C-arm image intensifier after informed written consent.

\textbf{Surgical technique}

General anaesthesia was employed for all cases. The patient was positioned supine on the operating table with affected limb being placed on a side table. Under the guidance of a sterile draped C-arm image intensifier, a step-wise closed manipulation was performed. Assessment of reduction was done clinically by assessing the carrying angle and radiologically by taking anteroposterior, lateral and Jones views.

Maintenance of reduction was achieved by passing two crossed K-wires from both the medial and lateral epicondyles or by passing two K-wires from the lateral condyle in parallel or crossed fashion. When crossed pinning was employed, the lateral pin was inserted first so that, the medial pin can be placed with the elbow in less flexion to avoid ulnar nerve injury.

The choice of crossed or lateral pin fixation was made according to the operating surgeon’s personal preference. Severe edema and reductions which needed hyperflexion of elbow were fixed with lateral pinning where crossed pinning had a significant risk of IUNI. Once the pins were in place, the elbow was extended and the adequacy of reduction was assessed in both planes.

After leaving about 1cm of the pins outside the skin, pins were cut off and bent and a well-padded posterior above elbow slab was applied with elbow flexed to 90 degrees or less as tolerated. Immediately in the postoperative period, the neurovascular status of the limb was assessed.
Limb was immobilized in posterior slab with elbow in 60-80 degree of flexion depending upon the swelling and neurovascular status. Patients were reassessed for their neurovascular status and also for any latrogenic nerve injuries and were all discharged within 48 hours of surgery.

Patients were called after one week for check X ray for any displacement and pin site infection, then after 4 weeks for removal of slab, check X ray and removal of K wires after union followed by physiotherapy for elbow. Active elbow exercises were started from fourth week as tolerated by the child. Passive motion and forceful manipulation were avoided. Follow-up was done regularly at six weeks, three months and end of six months. At the end of six months follow up, the clinical outcome was measured by Flynn's criteria & loss of reduction by Skagg's criteria (Table 2 & Table 3).

During the follow up period, pain, restriction of motion and satisfaction with appearance of elbow was assessed. Carrying angle and the range of flexion and extension of both the injuries and the normal elbow was measured with a goniometer and recorded. A neurological examination was performed to note recovery in case of neural deficit being noted previously. Statistical analysis was done by Chi-square test, T test and Fischer’s exact test.

RESULTS

The peak incidence was in 5-8 years age group with an average age of 6.75 years. In our study, incidence in male children was 60% and 40% in females. The common mechanism of injury in our series was fall on an outstretched hand (80%). In our study, there was 65% incidence of posteromedial displacements and 35% posterolateral displacement. Ipsilateral associated injuries were present in 6 cases (11%). The injuries were three distal radius fractures, two isolated fracture of ulna and one with fifth metacarpal fracture.

The average hospital stay for a patient in our study was 3 days with a range of 1 to 7 days. The minimum duration of six months of follow up in our study was adequate to assess fracture union, malalignment, range of motion and recovery from nerve injuries. The follow up ranges from six months to eighteen months.

The functional & cosmetic outcome was measured using Flynn's criteria, in lateral pinning twenty children (74%) had excellent grading (Figure 3) and seven children (26%) had good grading in view of loss of carrying angle. In cross pinning, twenty two children (78%) had excellent grading (Figure 4) and six children (22%) had good grading.

![Figure 3: a) Pre operative b) post operative radiograph with a two lateral pin fixation c) six month follow up clinical picture with excellent outcome according to flynn's criteria.](image)
there was no cubitus varus deformity in either group in our study and children were satisfied with the cosmetic appearance of their elbows. The difference in functional outcome between two groups was not statistically significant ($X^2=0.837, p=0.386$). All fractures united well. and maintain an anatomic reduction of the distal humerus to minimize complications such as nerve injury, compartment syndrome, Volkmann ischaemic contracture, cubitus varus deformity and limitation of elbow movements.

The advantage of using criss-cross pinning is to increase the stability of the fracture fixation thus decreasing the potential for loss of reduction, but simultaneously it carries increased risk of IUNI due to placement of the medial pin. Lateral pin configuration has the advantage of avoiding IUNI, but this construct has been thought to be biomechanically less stable.

In our study, IUNI was 11%. In literature, Arino et al reported that it was almost 21%, ulnar nerve deficit. In other study it was found in 15% of patients who were treated with medial and lateral pin as per the report of Chai.

Sankar et al studied the loss of pin fixation in supracondylar fractures. In all cases, loss of fixation was due to technical errors that were identifiable intraoperative fluoroscopic images and that could have been prevented with proper technique. He identified three types of pin-fixation errors: (1) failure to engage both fragments with two pins or more, (2) failure to achieve bicortical fixation with two pins or more, and (3) failure to achieve adequate pin separation (>2 mm) at the fracture site.

Skaggs et al showed failure of "lateral-entry pin fixation" technique is mainly due to technical errors. He suggested to maximize pin separation at the fracture site, to engage both columns proximal to the fracture, and to engage sufficient bone in both segments. He also suggested surgeons should have low threshold for using the third lateral pin.

From this retrospective analysis, both fixation techniques were good in terms of stability, function and cosmetic outcome. The problem with cross pinning was IUNI due to medial pinning. So lateral pinning is reliably safe method and provides adequate stability in displaced supracondylar fractures.

**ACKNOWLEDGEMENTS**

Authors would like to thank all patients for their cooperation in study. We also thank Gnanasundaram R, Tiwari RK for typing the manuscript.
